The conventional wisdom is (i) that fiscal austerity was the main culprit for the recessions experienced by many countries, especially in Europe, since 2010 and (ii) that this round of fiscal consolidation was much more costly than past ones. The contribution of this paper is a clarification of the first point and, if not a clear rejection, at least it raises doubts on the second. In order to obtain these results we construct a new detailed “narrative” dataset which documents the size and composition of the fiscal plans implemented by several countries over 2009–13. Out of sample simulations, that project output growth conditional only upon the fiscal plans implemented since 2009, do reasonably well in predicting the total output fluctuations of the countries in our sample over the years 2010–13 and are also capable of explaining some of the cross-country heterogeneity in this variable. Fiscal adjustments based on cuts in spending appear to have been much less costly, in terms of output losses, than those based on tax increases. Our results, however, are mute on the question whether the countries we study did the right thing implementing fiscal austerity at the time they did, that is 2009–13.

—Alberto Alesina, Omar Barbiero, Carlo Favero, Francesco Giavazzi and Matteo Paradisi
1. INTRODUCTION

The deficit reduction policies (often referred to as fiscal “austerity”) followed by several OECD countries in 2009–13 were designed to offset the expansionary increase in government spending sparked in previous years by the subprime lending crisis. They were certainly not adopted because the economy was weak and predicted to fall further: Rather they were implemented while recessions were not quite over and a credit crunch was still getting in the way of the recovery. The aim of this paper is to provide an empirical measure of the effects of these deficit reduction policies on output growth. The Fall of 2014, when we write, is probably the earliest time when one can begin to assess the effects of these policies.
We analyse the main features of fiscal adjustment policies, starting from their composition: How they were divided between tax increases and spending cuts, and what has been their cost in terms of output losses. We also examine whether this round of fiscal adjustments, which occurred after a financial and banking crisis, has had different effects on the economy compared with earlier fiscal consolidations carried out in “normal” times. In addition, contrary to previous episodes of fiscal consolidation, this time many countries implemented deficit reduction policies all at the same time, possibly deepening their recessionary effects due to interdependence of their economies.

We proceed as follows. We start by documenting in detail “how” austerity has been implemented in each country. This is not an easy task: Fiscal adjustment plans have often been complex, extending over several years, repeatedly modified in mid-course, sometimes even drastically because of political bickering. Then, we evaluate the effects of such policies on output growth. Since the fiscal corrections implemented in the years 2009–13 (as most fiscal corrections) came, as we said, in the form of multi-year plans, rather than 1-year moves, we need a model capable of simulating the effects of plans rather than isolated shifts in fiscal variables. We estimate such a model with data running up to (but not including) the years 2009–13. Then we simulate the model out of sample (i.e. over the years 2009–13) feeding in the actual plans adopted in those five years. This strategy allows us to analyse not only the output effects of austerity as actually implemented, but also to ask what the effect on output growth would have been, had the same fiscal contractions been implemented in a different fashion, e.g. relying less on tax increases and more on spending cuts.

Our main finding is that fiscal adjustments based on cuts in spending are much less costly, in terms of output losses, than those based on tax increases. Our evidence indicates that the difference between the two types of adjustment is very large. Over our estimation period (1978–2007) the average tax-based (TB) adjustment plan with an initial size of 1% of GDP results in a cumulative contraction in GDP of 2% in the following three years. On the contrary, spending-based adjustments generate very small recessions with an impact on output growth not significantly different from zero. In this respect, the recent episodes of austerity do not look different from previous ones. Out of sample simulations of our model, that project output growth conditional only upon the fiscal plans implemented since 2009, do reasonably well in predicting the total output fluctuations of the countries in our sample over the years 2010–13, and they are also capable of explaining some of the cross-country heterogeneity in this variable. The results are particularly strong for those countries in which the main shock in that period was indeed a fiscal policy one. For example, the TB adjustment implemented in Italy in 2010–13 is sufficient by itself to explain the recession experienced by the country over the period 2011–2 (with negative GDP growth of around 2% in each year).

When we test explicitly the hypothesis that recent fiscal adjustments had the same effect on output growth as past ones, we do not reject the null, although in some cases failure to reject is marginal. In other words, we don’t find sufficient evidence to claim that the recent rounds of fiscal adjustment, when compared with those occurred before the
crisis, have been especially costly for the economy. This evidence suggests that the fiscal multipliers estimated using data from the pre-crisis period give valuable information about the amount of output loss associated with the post-crisis fiscal consolidation measures. Blanchard and Leigh (2013a) come to a different conclusion: They argue that the costs of fiscal adjustments have been higher in recent years than previously estimated and therefore expected. The difference between our results and theirs depends upon the fact that we construct forecast errors which are conditional only upon deficit-driven fiscal consolidations. Instead, the forecast errors constructed in Blanchard and Leigh are conditional upon a scenario for all the exogenous variables that enter the IMF forecasting model they use. To put it differently, if the current rounds of fiscal adjustments had been marginally more costly than before (although the evidence is murky on this point) this difference would be explained by concurrent variables, say the credit crunch, not by a change in fiscal multipliers between the years before and after the crisis.

It is important to note from the start that this paper has nothing to say about the optimality of the fiscal adjustments implemented over the years 2009–13. Our more limited goal is to show that there was significant heterogeneity in the effects of such policies depending on their composition, taxes versus spending. Our work is thus related to that of Beetsma et al. (this issue) who show that the heterogeneous effect of fiscal adjustments on output growth is strictly related to their heterogeneous effect on confidence. Optimal policy can be discussed only within the framework of a structural model. The objective of our empirical paper is to highlight empirical evidence to be matched by structural models. The evidence we propose here can be used to select among different structural models; it cannot be used to discuss optimal policy.

This paper builds upon an earlier literature which had tried to assess the costs of fiscal adjustments using data up to 2007. That literature faced two key challenges. One was how to identify exogenous shifts in fiscal policy, namely shifts determined purely by the need to reduce excessive deficits and not as a response to the state of the economic cycle. The second challenge was to isolate the effect of fiscal policy from many other intervening factors such as devaluations, monetary policy, labour, and product market reforms, etc. This earlier literature, surveyed in Alesina and Ardagna (2010), used large changes in the cyclically adjusted budget deficit as a measure of exogenous fiscal adjustments. Using various samples and various modelling choices, these papers consistently found that fiscal consolidations based on spending cuts had been much less costly than those based on tax increases. In fact, in some cases, spending cuts were even slightly expansionary, that is associated with almost immediate increases in growth, thus confirming much earlier findings by Giavazzi and Pagano (1990). Concerning the importance of accompanying policies, Alesina and Ardagna (2013) investigated to what extent such policies, in particular labour market reforms, have helped the success of some fiscal adjustments. While devaluations in some cases did help (see Ireland in 1988) they were not consistently the driving force of successful adjustments. Perotti (2013) also emphasizes how critical accompanying policies are, arguing that one should never study budget cuts in isolation from other policy changes.
Cyclically adjusted budget numbers, however, are unable to filter out all fiscal policy actions correlated with the cycle. For instance, discretionary measures adopted in response to a recession are not filtered out of cyclically adjusted numbers. This methodology is thus suggestive, but imperfect. The limitations of studies that identify shifts in fiscal policy using cyclically adjusted budget numbers have been overcome by the “narrative” method pioneered by Romer and Romer (2010). These authors use original sources (budget documents, records of Congressional debates, etc.) to identify episodes of changes in US tax rates that were not dictated by the cycle, but were motivated either by the aim of improving “long-run growth” or of reducing an inherited deficit. Applying this identification strategy, Romer and Romer (2010) estimate large tax multipliers; over the course of three years an increase in taxes equivalent to 1% of GDP lowers output by 3%. Devries et al. (2011) have used this methodology to construct a narrative time series of shifts in fiscal policy (in this case both taxes and spending) for 17 OECD countries since the early 1970s. The shifts in taxes and spending identified by these authors are solely motivated by the need to reduce an inherited deficit – a definition that fits precisely the fiscal consolidation episodes adopted in Europe since 2009–10. Guajardo et al. (2014) have used these data to estimate fiscal multipliers and also find that TB adjustments were more costly, in terms of output losses, than expenditure-based (EB) ones, a result consistent with the earlier literature based on cyclically adjusted deficits.

Alesina et al. (2014, AFG in what follows) use the fiscal consolidation episodes identified by Devries et al. (2011), but propose a methodological innovation. They start from the observation that the shifts in taxes and spending that contribute to a fiscal adjustment almost never happen in isolation: They are typically part of a multi-year plan, in which some policies are announced well in advance, while other are implemented unexpectedly and, importantly, both tax hikes and spending cuts are used simultaneously. Also, as these plans unfold, they are often revised and these changes have to be taken into account as they constitute new information available to economic agents. AFG show that ignoring the connections between changes in taxes and expenditures, and between unanticipated and announced changes, might produce biased estimates of the effects of fiscal consolidations. Their results once again confirm a large difference between EB adjustments and TB ones. AFG also show that the shifts in monetary policy that accompany fiscal adjustments cannot explain the results – although this does not rule out the possibility that other contemporaneous economic reforms may make certain plans less costly than others.

The model estimated in AFG is the framework we use in this paper to estimate the effects of fiscal consolidations on output growth over the years preceding 2009 (the model is actually estimated using data up to 2007). We then simulate the model out-of-sample (i.e. over the years 2009–13) feeding in the actual adjustments plans implemented by ten

2 The size of their multipliers has been subjected to many discussions. See in particular Favero and Giavazzi (2012) and the survey by Ramey (2011b).
EU countries and by the United States in those five years. Finally, we shall run counterfactual experiments asking what the effect on output growth would have been, had the same fiscal contraction been implemented in a different fashion, for instance with less tax hikes and more expenditure cuts.

The paper is organized as follows. In Section 2, we present an overview of fiscal austerity in Europe after the crisis. In Section 3, we describe the construction of our data and we illustrate the way in which we identify fiscal plans. We describe in detail one case (Portugal) to illustrate our methodology. Detailed information on the plans adopted by all other countries is available in a Web Appendix. In Section 4, we present our model and our experiments. We first show the output effects of fiscal plans in the sample over which the model is estimated; we then show out-of-sample simulations, that is the results obtained feeding into the estimated model the actual adjustments implemented by each country in 2010–3; next we present the counterfactual experiment, and finally a discussion of robustness. Section 5 analyses the question whether recent fiscal adjustments have been more costly than earlier ones. The last section concludes.

2. FISCAL POLICY IN THE AFTERMATH OF THE FINANCIAL CRISIS

Many European economies did not enter the financial crisis with a clean fiscal slate. Before the crisis, debts and deficits were already high in several of them. One reason was the low interest rates of the first decade of the Euro, which had facilitated large debt build-ups in the European periphery. The country with the largest debt was Italy, with a ratio to GDP of 1.06 in 2008; Greece had a ratio of 1. But even countries with apparently better fiscal positions (such as Spain and Ireland) still had budget deficits, notwithstanding an exceptional (and unsustainable) level of revenues accruing from a real estate bubble. However, concerns about fiscal sustainability were not limited to the European periphery. Many countries faced the challenge posed by the rapid aging of their populations: Social expenditure had increased from an average of 18% of GDP in 1980 to 25% in 2009, with a rise of five percentage points of GDP in just the 10 years preceding 2009. Moreover, total government spending, even if reduced at the end of the 90s to meet the Maastricht criteria, was still high in 2007 (43% in 2007 in the EU average). The average share of public spending over GDP had increased from 34% in 1970 to 43% in 2007 in the OECD economies.

Government budgets, which were already structurally weak, worsened very significantly with the start of the financial crisis, in many cases because governments had to foot the bill of distressed financial institutions, Ireland being the most apparent example. The average deficit in the EU almost doubled between 2007 and 2008 reaching 6.4%

Besides automatic stabilizers, discretionary fiscal actions, aimed at slowing the rise in unemployment and protecting unemployed workers, played a crucial role, though to a different extent from country to country. The discretionary response was relatively small in Germany and Italy, while Spain, Portugal, the United Kingdom, and France implemented a large increase of the cyclically adjusted deficit (see Table 1).

Large increases in budget deficits meant that many European countries, around 2009, entered the EU Excessive Deficit Procedure, that is their fiscal policies started of GDP in 2009 (see Table 1). In the United States, the deficit increased from 2.7% to 13.3% of GDP. As a consequence debt ratios jumped: From 66.5% of GDP in 2007 to a projected 109.2% in 2014 in the United States; from 66.5% to 95.3% in the euro area (see Table 2). Besides automatic stabilizers, discretionary fiscal actions, aimed at slowing the rise in unemployment and protecting unemployed workers, played a crucial role, though to a different extent from country to country. The discretionary response was relatively small in Germany and Italy, while Spain, Portugal, the United Kingdom, and France implemented a large increase of the cyclically adjusted deficit (see Table 1).

*Source: IMF World Economic Outlook, April 2013 and IMF Fiscal Monitor, April 2013.*
being monitored by the European Commission.\(^8\) After the start of the Greek crisis, in the spring of 2010, there were renewed anxieties about the unsustainability of public debt in some European countries and investors demanded higher interest rates on government bonds: Yields spiked throughout the European periphery. At the same time, these pressures raised concerns in public opinions. The share of articles discussing fiscal consolidation was marginal during the first years of the financial crisis, but rapidly increased in 2010, typically reaching a peak around the end of 2011 (see Figure 1).\(^9\)

Responding to these pressures, most European countries began fiscal consolidations, enacting, starting in 2010, multi-year deficit reduction programmes, notwithstanding mediocre growth projections for the years to come.

Figure 2 shows how the fiscal policy of euro area economies changed overtime, in relation to the economic cycle. For every year we show the change in the cyclically adjusted primary balance and the level of the output gap. The first and third quadrants represent instances of counter-cyclical fiscal policy where governments squeeze the public budget while the economy is overheating, and vice versa. On the contrary, the second and fourth quadrants include years in which fiscal policy was pro-cyclical. The majority of the countries in the sample adopted counter-cyclical fiscal policies at the beginning of the recession (2008–9) but turned pro-cyclical after 2009, namely fiscal consolidations started when recessions were not over yet.

---

\(^8\) The United Kingdom entered the Excessive Deficit Procedure in 2008. In 2009, the countries entering the procedure were Spain, Greece, Ireland, France, Germany, Italy, Portugal, the Netherlands, Belgium, and Austria. Denmark entered in 2010.

\(^9\) Data on the share of articles regarding the fiscal consolidation debate were gathered from Factiva from January 2006 to January 2014.
Figure 1. Fiscal policy in media

Notes: The extent to which fiscal policy was debated in media is measured through the share of articles concerning fiscal policy over the total number of published articles. Data are monthly and the plotted series is a 5-year centred moving average of the measure in our sample. Numbers along vertical axis are the percentage over total articles published. Using the archive Factiva we searched for keywords connected to fiscal policy and debt: “austerity”, “fiscal consolidation”, “fiscal compact”, “Maastricht”, “excessive deficit procedure”, “public debt”, “fiscal policy”, “budget deficit”, and “debt crisis”. We collect monthly data for the countries in our sample from January 2006 to January 2014. We normalize the absolute number of articles dividing by the total number of published articles, measured by searching the most common word for each country (e.g. “the” for English-speaking countries). We select the first five national newspapers for circulation in every country excluding sport newspapers, free newspapers, and tabloids.

The evidence in Figure 2 raises a natural question on the optimality of such countercyclical fiscal actions. As discussed in the Introduction section, our paper cannot answer this question. We cannot pass judgement on the pros and cons and on the timing of the fiscal adjustments. Our more limited aim is to investigate whether the effects of such adjustments were affected, and to what extent, by their composition (taxes versus spending) and their persistence and predictability.

Together with these budgetary policies, structural reforms were also introduced in some countries. For instance, most of the countries in our sample implemented some labour and product market reforms (see OECD, 2014a). Spain introduced a very significant labour market reform (see OECD, 2014a); Italy, France, and Spain implemented
pension reforms in 2010 and 2011. Even though not driven by high borrowing costs, fiscal consolidation entered the policy agenda of some non-European economies as well. In the United States, the fear for the sustainability of the public debt – and the...

**Figure 2. Extent of pro-cyclical polices in advanced economies during and after the financial crisis**

Notes: We plot the change in the cyclically adjusted primary balance against the output gap registered in the same year. A negative (positive) change in the primary balance means that the cyclically adjusted deficit is increasing (decreasing). As a consequence, years of countercyclical fiscal policy are those in the first and third quadrants, while years of pro-cyclical policies lie in the second and fourth quadrants.

Source: OECD forecasting, analysis and modelling environment.

In Italy, the 2010 Budget Law raised the retirement age for old-age pensions for females working in the public sector starting from January 2012, introducing the same retirement age for men and women. In 2011, a new reform increased the old-age retirement age for women in the private sector from 60 to 62 years starting in 2012, with a gradual increase up to 66 years by 2018, whereas the male retirement age was increased to 66 years in 2012. Retirement ages and the seniority rules for early retirement were also indexed to life expectancy. On top of this, pension indexation was suspended for two years. Finally, the reform speeds up the transition from the defined benefit to the defined contribution schemes.

In France various measures were taken with the 2010 Pension Reform to encourage the employment of older workers. The mandatory retirement age was raised from 65 to 70 years; a wider use of the pension premium was introduced and a greater flexibility for combining earned and pension income was guaranteed. Moreover, the extension of the contribution period as a function of rising life expectancy was approved, although indexation is not automatic.

In Spain, the pension reform is implemented in 2011 with the first measures entering in office in 2013. The Reform increased the retirement age from 65 to 67 years, while early retirement was delayed from 61 to 63 years. Moreover, the number of years required to reach the 100% of the reference wage increased from 35 to 37 years of contribution.
downgrade of the US government bonds by S&P for the first time in history – was the main motivation behind the adoption of the measures included in the Budget Control Act approved in 2011 and the ensuing debate over the “Fiscal Cliff”. In the Web Appendix, we analyze these fiscal consolidation actions country by country. In the next section we show, using the example of Portugal, how we measure the fiscal plans adopted by each country, how we classify them as TB or EB, and how we account for their changes over time.

Eventually, in 2013, the year our analysis stops, the intensity of the fiscal consolidation effort decreased almost everywhere in Europe – in part because some countries, such as Italy, Ireland, and Portugal, were able to exit the Excessive Deficit Procedure, in part because Mario Draghi’s famous words, “We will do whatever it takes”, resulted in a significant reduction in borrowing costs and alleviated the risk of a debt crisis.

3. FISCAL CONSOLIDATIONS IN 2009–13

3.1.Constructing and classifying fiscal plans

The fiscal consolidations implemented in 2009–13 were multi-year fiscal plans. We measure and classify these plans extending the database running from 1976 to 2007 that was constructed by AFG for 17 OECD countries. The plans in AFG were in turn constructed reclassifying the annual shifts in fiscal policy – not driven by an output stabilization motive – identified by Devries et al. (2011), whose assumptions we discussed in the Introduction section. Since the Devries et al. (2011) data stop in 2007, we follow their methodology to identify the exogenous shifts in fiscal policy occurred after 2009, and then use them to build fiscal plans following the methodology of AFG.

Fiscal plans are combinations of unexpected and announced fiscal corrections. When a Parliament votes a deficit reduction policy at time $t$ and implements it in the same year, we call it unexpected: $\epsilon^{u}$. The latter represents a reduction of the deficit over GDP ratio. This reduction may come from a reduction in spending over GDP ratio (denoted by $g$) or an increase in the tax revenues over GDP ratio (denoted by $\tau$). When a correction is voted by Parliament in year $t$ but is implemented in year $t + k$ (where $k$ is the anticipation horizon), it is called announced, with horizon $k$: $\epsilon^{a}_{t,k}$. As time goes by, and a correction announced in year $t$ for year $t + k$, $\epsilon^{a}_{t,k}$, comes closer to the date of implementation, its horizon is correspondingly reduced: $\epsilon^{a}_{t+1,k-1}$. The shift in the index of the announced adjustment continues until the adjustment is actually implemented in year $t + k$. In that year it is labelled $\epsilon^{a}_{t+k,0}$. All the deficit reduction polices, both announced and implemented, are divided in tax increases and spending cuts, both measured as fraction of GDP. After plans have been constructed we distinguish between TB and EB plans. We

---

11 In principle even a policy announced and implemented immediately might have been expected, but without an official announcement it is virtually impossible to measure the degree of surprise of a new policy, as disused in more detail in AFG.
label a fiscal adjustment, respectively, as TB and EB if the sum of the unexpected plus
the announced tax (expenditure) changes (measured as percent of the GDP of the year
the plan is introduced) is larger than the sum of the unexpected plus the announced ex-
penditure (tax) changes. Note that since plans sometime change in mid-course – due to
political bickering or because a government falls and is followed by a new one – a plan
that started, say, as EB may turn into a TB one, or the other way around. In Section
4.3.3, we explore a different way of classifying fiscal adjustments abandoning the TB
and EB dummy definitions and exploiting separately the magnitude of revenue and ex-
penditure changes. Our empirical results are robust to this reclassification.

The countries that we consider are Austria, Belgium, Denmark, France, Germany,
Great Britain, Ireland, Italy, Portugal, Spain, and the United States.\footnote{12}

We now show how, using this framework, we have constructed fiscal consolidation
plans over the years 2009–13 for each country in our sample. We start, in Table 3, pro-
viding some descriptive statistics.

### 3.2. Fiscal consolidation plans after the financial crisis

The countries in our sample can be divided into three groups. The first includes the
countries in the core of the euro area that on average experienced less serious financial
trouble; the second includes countries in the periphery; the third group includes three
countries outside the EMU, which we use as examples of advanced economies with flex-
ible exchange rates.

\footnote{12 Greece and Cyprus have been excluded because the data required to include these countries in the
panel used to estimate the model were not available – and if they were, as could be the case of Greece,
such data have since been extensively revised.}

Notes: The column “Average Consolidation Impact” displays the average impact computed only over the total
number of episodes in each country between 2009 and 2013. The last column weight each EB event employing
the size of the consolidation. The total number of events is 42 and only ten of them are TB.
To identify exogenous shifts in fiscal policy we used the Stability and Convergence Reports of the European Commission, national budget reports, central bank reports, and Congressional Budget Office documents and Economic Reports of the President for the United States. The detailed motivations for the deficit-driven fiscal consolidation plans from 2009 to 2013 and a description of how we retrieved the data are available in the Web Appendix. Box 2 discusses the differences between our narrative shocks and the cyclically adjusted measures, and compares our data with other narrative measures.

We illustrate our methodology with the example of Portugal. In the Web Appendix we show how the same procedure was applied to all other countries in our sample.

</table>

Portugal started a very aggressive fiscal consolidation plan in 2010, under financial pressure on government bonds and liquidity concerns. Between 2010 and 2013 the measures adopted amounted, on average, to about 3.5 percentage points of GDP per year for 4 consecutive years: This can be seen in the table above summing the terms $\epsilon^u$ and $\epsilon^u_{1+k,0}$ thus computing the direct impact on the budget of each year of the measures adopted. In 2010, the budget deficit was reduced by 1.16% of GDP, of which 0.63% of revenues increase ($\tau^u_{2010}$ in the table above) and 0.53 of spending cuts ($\mu^u_{2010}$). Expenditure cuts involved wage restraints for civil servants, some cuts to social benefits and reductions to the operating expenditure of ministries. Revenue increases included an increase in the VAT rate and an increase in personal and corporate income taxes. The same 2010 Budget also introduced new expenditure cuts amounting to 1.41% of GDP and new tax increases of 1.43% to be implemented in 2011 (they are, respectively, $\tau^u_{2010,1}$ and $\mu^u_{2010,1}$). These announcements anticipated a further tightening of the 2010 expenditure measures and limitations to benefits and allowances related to the personal income tax. The first row of the above table illustrates the way in which we use this narrative record to construct the 2010 fiscal plan.

The sovereign debt crisis began in Portugal in November 2010, when the yield on the country’s 10-year government bonds reached 7%. In April 2011, Prime Minister José Sócrates, who had resigned and was heading a transition government, announced that the country would request financial assistance. In May 2011 when the interest rates on debt had reached 10%, Eurozone leaders approved a €78 billion bailout package for Portugal. As part of the deal, the country agreed to cut its budget deficit from 9.8% of GDP in 2010 to 5.9% in 2011, 4.5% in 2012, and 3% in 2013.

Note, in our table, that in 2011 a more comprehensive and longer adjustment programme was designed as a condition for economic and financial assistance. The 0.6% of GDP of unexpected expenditure cuts focused on public sector wages and public
investments. The 0.5% of GDP of unexpected tax consolidation mainly involved a personal income tax surcharge on workers’ 13th salary.

The fiscal consolidation plan included more spending-based measures to be implemented by 2013. However, in both 2012 and 2013, the plan was modified with unexpected changes in the anticipated components of previously approved budgets.

The last two columns of the table show that this classification strategy leads to label the Portuguese plan in 2010 and 2013 as TB, and in 2011 and 2012 as EB. It is not uncommon for a plan to change its nature over time. In the case of Portugal, the change from EB to TB in 2013 was mostly due to the cancellation of some announced expenditure cuts (mostly reductions in public sector wages) by the Constitutional Court in June 2012. In order not to miss the deficit targets, the Portuguese government compensated these vanished expenditure cuts with new tax measures involving a revision of the personal income tax structure resulting in a reduction in the number of brackets, combined with a 4% general surcharge of taxable income and a 2.5% solidarity tax on the highest tax bracket. This is clearly visible in the change from $s_{2011,2} = 0.4$ to $s_{2012,1} = 2.1$ and from $g_{2011,2} = 1.4$ to $g_{2012,1} = 0.8$ that in turn causes the plan to be predominantly TB in 2013.

In 2013, the government implemented a debt recovery scheme for overdue tax and social security contributions, to be implemented before the end of the year and coded as an unexpected 0.4 shift. Given the one-off nature of this scheme, we code its reversal in the following year as a negative announcement: $s_{2013,1} = -0.4$. Moreover, even though in April 2013 a further Constitutional Court decision ruled out cuts worth 0.8% of GDP, these were totally compensated by the frontloading of 0.8% of GDP from the expenditure review programme.

In the Web Appendix we go over each country’s experience as we did here for Portugal and we illustrate the methodology and the sources we used to construct our fiscal plans.

Before moving to our results a few observations are in order.

1. The size of the fiscal adjustments in many countries was large, especially in Spain, Ireland, and Italy, in addition to Portugal as we have seen. In other countries, like Great Britain or Belgium, it was more moderate. In others (Germany and the United States) it was relatively small. Ireland hit a 30% deficit over GDP ratio in 2010 as a result of the bail out of banks, but even leaving this episode aside, the Irish adjustment was very large.

2. Even in those countries with large adjustments (say Spain and Portugal) the size of them was not unprecedented in recent history. As shown in Table 3, Column 3, the average consolidation impact is 3.4% of GDP per year in Portugal, a size that has been observed on several occasions in our estimation sample, e.g. Italy 1992, Denmark 1983, Sweden 1995, Ireland 1982.

3. In certain countries (Ireland and Spain for instance) banking crises were the main determinants of the fiscal imbalances. In others (Portugal or Italy for
instance) deficits and accumulated debts were the main drivers. In either case however the key exogeneity assumption regarding the cycle is preserved.

4. The composition of adjustments between spending cuts and tax hikes varied across countries. For instance in the case of Italy the adjustments were all TB (at least until 2013). In the case of Ireland and Great Britain they were mostly spending-based. Spain was somewhere in between although more on spending than on taxes.

5. The plans are generally a combination of expected and unexpected fiscal changes. Only in the case of Ireland there were no announcements of future policies during the adjustments.

6. Many plans were revised in mid-course several times, as a result of political bickering. In Italy for example three different governments were in office between 2009 and 2013, including a “technical” one appointed with the specific task of improving the fiscal stance of the country at a moment when it was on the verge of fiscally imploding.

7. In Italy, Spain, and France pension reforms were implemented with potential savings accruing in future years. Probably the sharpest one, in terms of expected fiscal savings, was implemented in Italy.

8. Spain introduced a reform to liberalize the labour market. Hardly any other structural reforms were implemented in any other country, at least until 2013 included.

9. In the United States the discretionary fiscal measures were implemented as a result of the extremely hot debate over the so-called “fiscal cliff”. Despite the rhetoric in the debate, in the end the discretionary actions taken were very small.

4. THE OUTPUT EFFECTS OF FISCAL CONSOLIDATIONS

The analysis of the output effects of economic policy requires – for the correct estimation of the relevant parameters – identifying policy shifts that are exogenous with respect to output fluctuations. In the context of fiscal policy the concepts of exogeneity and identification are illustrated in Box 1 and further discussed in the Appendix. As we already mentioned, for the sample used to estimate our model (1981–2007) we identify fiscal stabilizations designed to offset changes in government spending implemented in the past. Such stabilizations are not motivated by contemporaneous cyclical fluctuations and are therefore likely to be exogenous with respect to output growth. In practice we use the “narrative” data collected by Devries et al. (2011) and revised in AFG. By construction these fiscal adjustments are predictable by previous fiscal expansions. There is also evidence that fiscal adjustments identified with the narrative method are predictable from their own past (see the Appendix). We interpret this evidence as a consequence of the fact that fiscal policy is conducted through multi-year plans and we show how plans and their output effect can be correctly estimated and simulated. Predictability and exogeneity are not the same concept as we discuss in Box 1.
Box 1. The identification of exogenous fiscal plans

Exogeneity of the shifts in fiscal policy for the estimation of their output effect means that they should not be correlated with news on output growth, i.e. with the cycle.

The traditional steps to identify such exogenous shifts involved first the estimation of a joint dynamic model for the structure of the economy and the variables controlled by the policy-makers (typically a VAR). The residuals in the estimated equation for the policy variables approximate deviations of policy from a rule. Such deviations, however, do not yet measure exogenous shifts in policy because a part of them could represent a reaction to contemporaneous information on the state of economy. In order to recover structural shocks from VAR innovations some restrictions are required. In the case of monetary policy identification can be achieved exploiting the fact that central banks take their policy decisions at regular intervals (e.g. there are eight FOMC meetings every year) and there is consensus on the fact that it takes at least one period between two meetings before the economy reacts to such decisions. This triangular structure – innovations in the monetary policy variable reflect both monetary policy and macroeconomic shocks, but macroeconomic variables are not contemporaneously affected by monetary policy shocks – is sufficient for identification.

Fiscal policy is different, in the sense that it is conducted through rare decisions and, as discussed in the main text, is typically implemented through multi-year plans. Such plans generate “fiscal foresight”: Agents learn in advance announced measures to be implemented in the future. The consequence is that the number of shocks to be mapped out of the VAR innovations is too high to achieve identification; technically the Moving Average representation of the VAR becomes non-invertible.

As a consequence of this specific feature of fiscal policy, after initial efforts at adapting the identification scheme used for monetary policy, attempts at mapping VAR innovations into fiscal shocks have become less successful and an alternative strategy has emerged, which is based on a non-econometric (narrative) identification of the shifts in fiscal variables. These are then plugged directly into an econometric specification capable of delivering the impulse response functions that describe the output effect of fiscal adjustments. In this “narrative” (Romer and Romer 2010) identification strategy legislated tax and expenditure changes are classified into endogenous (induced by short-run countercyclical concerns) and exogenous (responses to an inherited budget deficit, or to concerns about long-run economic growth or politically motivated). In this paper we concentrate on fiscal measures designed to deal with inherited budget deficits, therefore we concentrate on the effect of a subset of all exogenous adjustments.
Starting from narratively identified shifts in fiscal variables we build fiscal plans recognizing that such plans generate inter-temporal and intra-temporal correlations among changes in spending and revenues. The inter-temporal correlation is the one between the announced (future) and the unanticipated (current) components of a plan – what we shall call the “style” of a plan. The intra-temporal correlation is that between the changes in revenues and spending that determines the composition of a plan. As argued by Ramey (2011a) and Ramey (2011b) distinguishing between announced and unanticipated shifts in fiscal variables, and allowing them to have different effects on output, is crucial for evaluating fiscal multipliers. This approach, first introduced in AFG, is an advance on the literature which so far had studied (see e.g. Mertens and Ravn 2011) the different effects of anticipated and unanticipated shifts in fiscal variables assuming that they are orthogonal.

As discussed in the main text, a fiscal plan is specified by making explicit the relation between the unpredictable component of the plan and the other two components. In particular, with reference to a specific country \(i\), we consider:

\[
e_{i,t,1}^a = \varphi_{1,i}e_{i,t}^B + v_{1,i,t}
\]

\[
e_{i,t+1,0}^a = e_{i,t,1}^a
\]

The first equation is a behavioural relation that captures the style with which fiscal policy is implemented. Countries that typically implement “permanent” plans will feature a positive \(\varphi_{1,i}\), while temporary plans (in which a country announces that an initial fiscal action will be reversed, at least partially, in the future) will feature a negative \(\varphi_{1,i}\).

Our approach thus constructs the output response to a fiscal plan by allowing for a different effect between unanticipated and anticipated corrections, and by recognizing their interdependence within plans. Note that the very nature of a plan makes shifts in fiscal variables predictable. Finally within this framework we also allow for the infra-temporal correlations of plans, that is, for heterogeneous effects of TB and EB fiscal adjustments.

The fiscal plans studied in this paper are constructed expanding the data put together, using the narrative method, by Devries et al. (2011). These authors, however, differ from us in that they opt for aggregation, summing up anticipated and unanticipated components. Jordà and Taylor (2013) have observed that such aggregated shifts in fiscal variables (hereafter referred to as “IMF shocks”) are not exogenous, and therefore are not valid instruments because they can be predicted using their own past (strongly), past values of output.
When fiscal policy is conducted in country $i$ through multi-year plans, narrative exogenous fiscal adjustments in each year, $f_{i,t}$, include three components: Unexpected adjustments (announced upon implementation at time $t$) $e_{i,t}$, past announced adjustments (implemented at time $t$ but announced in previous years) $e_{i,t,0}$, and future announced corrections (considering, for simplicity, the case in which the horizon of the plan is only 1 year, these corrections are announced at time $t$ for implementation at time $t+1$) $e_{i,t,1}$.

$$f_{i,t} = e_{i,t} + e_{i,t,0} + e_{i,t,1},$$

where the letter $e$ represents the sum of the two components of a fiscal adjustment: tax increases and spending cuts.

A fiscal plan is specified by making explicit the relation between announcements and the other two components of a plan. In particular, we consider

$$
e_{i,t,1} = \phi_{1,i,t} e_{i,t} + v_{1,i,t},$$

$$
\phi_{i,t+1,0} = \phi_{1,i,t,1}.
$$

The first is a behavioural relation that captures the style with which fiscal policy is implemented. More permanent plans will feature significantly positive $\phi_{1,i,t}$, while a temporary plan (to be reversed, at least partially in the future) will feature a significantly negative $\phi_{1,i,t}$.

The second relationship simply states that the announced correction implemented at time $t$ is equal to what was announced in the previous period with a fiscal foresight of one period. Note that this does not imply that all announced corrections are implemented but it does imply that deviations of implemented corrections from those announced are always considered as surprises by all agents.

In the next section, we illustrate how we deal with plans in a model designed to measure their effect on output, and how use the estimated model to perform out-of-sample simulations.
4.1. The data

4.1.1. The pre-2009 data used in estimation

The AFG panel on which we run the “within sample” estimation includes 14 countries: Australia, Austria, Belgium, Canada, Denmark, France, Germany, Ireland, Italy, Japan, Portugal, Spain, the United Kingdom, and the United States. The frequency of the data is annual and the sample runs from 1981 to 2007. In the Devries et al. (2011) data, tax increases are measured as the expected revenue effect of each change in the tax code as a percent of GDP of the year the announcements made, whether it is implemented immediately or announced for a later period. Spending cuts are measured as changes in expenditure relative to the level that was expected absent the policy shift, not relative to the previous year. This means that a spending cut for year $t+1$ does not necessarily imply a reduction in government spending relative to year $t$, but only relative to what would have happened in year $t+1$ absent any policy changes. Announcements are assumed to be fully credible. A few measures that were announced but for which ‘the historical record shows that they were not implemented at all’ are dropped from the Devries et al. (2011) database. There are only five instances in our sample in which this happened – that is individual announcements were not recorded because never implemented – one each in Japan, Italy, Germany, the United Kingdom, and the Netherlands (a case that is irrelevant for us since, as we discuss below, we drop this country). In these cases we have not questioned the Devries et al. (2011) data call. All other announcements are assumed to be credible and, thus, recorded.

4.1.2. The data after 2009 used in “out-of-sample” simulations

In order to simulate the effects of the fiscal consolidations implemented after the start of the financial crisis we extended the Devries et al. (2011) panel following exactly the same methodology they employed. As discussed above in Section 3, our new data cover 11 countries in the period 2009–13. The countries are: Austria, Belgium, Denmark, Germany, France, Ireland, Italy, Portugal, Spain, United Kingdom, and United States. The total number of fiscal consolidation episodes is 42 (see Table 3).

---

13 The AFG data are based on a revision and reclassification of the original Devries et al. (2011) data. As a consequence some discrepancy arises between the two databases on occasion of few episodes. Such discrepancies are illustrated and commented in the Data Appendix in AFG.

14 Finland, Sweden, and the Netherlands were dropped in the estimation in AFG. Euro area countries such as Greece and Cyprus were also excluded for lack of (reliable) data. See that paper for more details.

15 At the estimation stage the sample is reduced to 1981-2007 because of the presence of leads and lags of the fiscal variables.

16 The US “Sequester” of March 2013 is one example.
Box 2: Comparison with cyclical adjusted measures and other narrative data

Cyclically adjusted and narrative measures of fiscal consolidation

Our narrative measure of fiscal policy notably differs from the cyclically adjusted measures employed in some part of the literature. In Figure 3, we plot our measure against (i) the change in the cyclically adjusted structural balance and (ii) the change in the primary balance for each country in our sample, as constructed by the IMF. The trend in the IMF structural measure is similar to ours and obviously less volatile than the uncorrected change in primary balance. Notice that in 2009 our measure is almost always equal to zero given that no exogenous consolidation policies were implemented.

Figure 3. Comparison between simple primary balance, structural primary balance, and narrative changes in fiscal policy

Sources: Data on simple primary balance and structural primary balance are taken from IMF World Economic Outlook Database, October 2013; narrative consolidation episodes are our extension of Devries et al. (2011) data.
The discretionary policies implemented in 2008–9 were part of fiscal stimulus plans intended to recover from the crisis and thus must be considered endogenous. Hence, contrary to our measure, the change in the cyclically adjusted structural deficit in 2009 is negative for almost every country. This raises a major concern about the use of changes in the cyclically adjusted structural balance for the identification of exogenous shifts in fiscal policies. Note in particular that the smallest differences between our data and the structural cyclically adjusted primary balance appear in countries which did not implement significant fiscal stimuli in response to the crisis, like Germany and Italy.

For the years after 2009–10 the trend in the IMF cyclically adjusted structural measure is very similar to our narrative data. However, it almost always lies below our narrative changes. This is due to several factors. First, implemented consolidation measures were sometimes mitigated by discretionary anti-cyclical measures (which we exclude from our analysis because endogenous). Second, our data refer to ex-ante predictions of policy impacts, while the IMF measures refer to ex-post deficit outcomes.

Other narrative measures

Dell’Erba et al. (2013) and Ağca and Igan (2013) have also constructed narrative data for the countries in our sample for the years 2010 and 2011. Dell’Erba et al. (2013) base their construction on the estimates provided by the 2011 OECD publication Restoring Public Finances. Ağca and Igan (2013) complement the Dell’Erba et al. (2013) using IMF Article IV Staff Reports, OECD Country Reports, and national budgets. Both these works, however, do not take into account the multi-year feature of fiscal plans and thus do not collect data about announcements. Moreover, they only cover the years 2010 and 2011 when fiscal consolidations were not as relevant as in 2012 and 2013. Indeed, only a few countries started fiscal adjustments in 2010, while all countries in our sample implemented fiscal actions in 2012 and 2013. Furthermore, the average size of fiscal consolidations in 2012–3 is around 2%, against 1.3% for 2010–11. Our narrative episodes for 2010 and 2011 do not differ significantly from their estimates.

4.2. The estimated model

In order to measure the output effect of fiscal consolidation plans, we estimate a multivariate system in which the output growth of each country is projected on the three (exogenous) components of a fiscal plan. This reduced form specification is a truncated moving average representation for output growth where the only innovations included...
are the fiscal ones. Of course, we are omitting many other structural shocks relevant to explain output growth. But under our identifying assumption, all omitted structural shocks are orthogonal to those that we include in the regression.\footnote{10}

The estimated system (\(i\) denotes the country) is the following:

\[
\Delta y_{i,t} = \alpha + B_1(L)e_{i,t}^u \ast TB_{i,t} + B_2(L)e_{i,t-0} \ast TB_{i,t} + C_1(L)e_{i,t}^u \ast EB_{i,t} + C_2(L)e_{i,t-0} \ast EB_{i,t} + \sum_{j=1}^3 \delta_{i,t}^a \ast TB_{i,t} + \sum_{j=1}^3 \delta_{i,t}^a \ast EB_{i,t} + \lambda_t + \chi_t + \mu_{i,t}
\]

\[
e_{i,t,j}^a = \varphi_{i,j}e_{i,t}^u + v_{i,t,j} \quad j = 1, 2, 3
\]

\[
e_{i,t,0}^a = \epsilon_{i,t-1,1}
\]

\[
e_{i,t,j} = \epsilon_{i,t-1,j+1} + (\epsilon_{i,t,j} - \epsilon_{i,t-1,j+1}) \quad j > 1
\]

Per capita GDP growth in each country \(\Delta y_{i,t}\) is affected by three different deficit reduction actions (as a percentage of GDP):

- approved and implemented in year \(t\) (unanticipated, \(e_{i,t}^u\));
- shifts that had been announced in the past, but come into effect at time \(t\) (\(e_{i,t,0}^a\));
- announced at time \(t\) that will be implemented in the future. We call these “anticipated” shifts in fiscal variables and consider a 3-year horizon (\(e_{i,t}^a\)). Three years is the average horizon of the fiscal plans in our sample.

\(B(L)\) and \(C(L)\) polynomials are truncated after three years: They represent the coefficients of the associated lagged variables from time \(t\) to \(t - 3\).\footnote{19} The model is estimated by Seemingly Unrelated Regressions imposing cross-country restrictions on the coefficients in \(B\), \(C\), and on the \(\gamma_s\) and \(\delta_s\). We also include year and country fixed effects. We gain in efficiency on the estimates of \(B\), \(C\), and on the \(\gamma_s\) and \(\delta_s\) by pooling together the data from several countries.\footnote{20} We allow for the possibility of within country
heterogeneity in the response of output growth to TB and spending-based adjustments interacting overall fiscal shocks with TB and EB dummies.

Once the model is estimated we simulate the effect of an unanticipated shift in fiscal variables preserving the inter-temporal dimension of country-specific fiscal plans. That is, when we simulate the effects on output growth of an unanticipated shift, say in taxes, we recognize that a country’s typical fiscal plan accompanies unanticipated shifts in taxes with the announcement of future shifts in taxes and/or spending. We build such “artificial” announcements adding to the estimated model the following country-specific additional equations:

$$
\epsilon_{i,t,j}^a = \phi_{i,j} \epsilon_{i,t}^a + v_{i,t,j}
$$

where $i$ refers to the country, $t$ is the period, and $j = 1, 2, 3$ is the horizon (limited to 3 years) of fiscal announcements. Allowing the $\phi_{i,j}$ to differ across countries (i.e. allowing for countries to implement fiscal plans that are on average different from one country to another) we introduce an additional source of heterogeneity: “between” countries heterogeneity that relates to the “style” of fiscal plans, meaning the correlation between their unexpected and announced components. The estimation of a country’s style allows us to distinguish between countries that pursue consistent stabilization efforts over time, countries with 1-year horizon plans and finally countries in which the $\phi_{i,j}$s are negative, i.e. where announcements tend to overturn the effects of unanticipated shifts in policy.

In the specification illustrated above we interact overall fiscal shocks with the TB and EB dummies, rather than introducing $\tau_t$ and $g_t$ separately. We do so because this version of the model is more suitable for simulating average plans and for interpreting their results. The reason is that it avoids the problem of estimating the contemporaneous correlation between taxes and spending measures. In other words, the introduction of $\tau_t$ and $g_t$ directly into the specification would require the estimation of a very large number of $\phi_{i,j}$ parameters. This drawback does not apply to TB and EB corrections, since by construction TB is equal to zero when EB is equal to 1 and thus no interaction between these corrections need to be estimated. On the other hand, the model with the TB and EB dummies may be sensitive to the categorization of plans into EB and TB, especially when the share of spending and taxes over the total consolidation is around 50%. Reassuringly, the majority of the plans in our estimation and simulation samples are far from a fifty–fifty split. In the estimation sample the share of spending cuts in the average EB plan (in which the average total annual adjustment is 1.36 of GDP) is 84%, while in the case of TB plans (in which the average total annual adjustment is 0.89 of GDP) such a share is 76%. In the simulation sample there are only two cases (over 42) where the share of spending is between 49% and 51% of the total consolidation, and eight cases where the share is between 45% and 55%. In any event, in Section 4.3.3 we present estimates of the model in which we introduce $\tau_t$ and $g_t$ separately. The results obtained
introducing $\tau_i$ and $g_i$ separately are qualitatively very similar to the ones obtained with the benchmark model (these results are reported below).

To sum up, the model can serve two different purposes. First, as in AFG, we can estimate within-sample the output effect of the average consolidation plans occurred during the estimation period. In other words, we compute impulse responses of output with respect to plans, in order to measure their effects. These impulse responses are computed as the difference between the simulated output growth conditional on the \textit{average} EB and TB plan, and the simulated output growth when no fiscal stabilization is implemented. Second, once the model is estimated, we can run out-of-sample simulations of \textit{specific} adjustment plans feeding directly into the model the announced and realized components of a given plan – rather than using the estimated $\varphi_{ij}$ to simulate the average within-sample plan. This second exercise produces projections of output growth conditional on the specific fiscal plan studied.

Our specification uses a parsimonious representation to simulate the output effect of fiscal plans. The same problem has been addressed using a different methodology (the Local Projections Method) in Jordà and Taylor (2013) and Jordà (2005). We illustrate and evaluate these two alternative approaches in the Appendix. The main difference between the two is that Jordà and Taylor deal econometrically with the different degree of predictability of plans collapsed into exogenous single-period corrections, while our method preserves the inter-temporal, multi-period aspect of fiscal adjustments and trace the effect on output of fiscal stabilizations that, despite being predictable, are exogenous with respect to the cycle.

4.3. Results

We organize the presentation of our empirical results in two sub-sections. First, we describe the estimation and impulse response function corresponding to the average plan implemented during 1981–2007. We then concentrate on the main contribution of the paper: The out-of-sample simulations of the output effect of the consolidation plans adopted after the crisis.

4.3.1. Output effects of fiscal plans: pre-crisis (in-sample results)

Estimated coefficients for our model over the period 1981–2007 are reported in Table 4. Note the negative sign on all significant TB adjustments implying that tax hikes have a negative and significant effect on output. The positive and in some cases statistically significant coefficients on the EB adjustments mean that spending cuts are correlated with an increase in output (only one of the EB coefficients is negative and then only marginally significant: The effect of the implementation today of a spending cut announced in the past).\footnote{Our data refer to the general government accounts for all countries except Australia, Canada and the US, where they refer to the federal government. Thus, reductions in transfers from the central government are treated as a tax hike rather than a spending cut.}
We summarize the results reporting, in Figure 4, the response of output to a 1% unexpected fiscal consolidation shock. We consider the effects of EB and TB adjustments separately (in squares and circles, respectively). When simulating an unexpected shock, we accompany it with “artificial” announcements of future policy shifts constructed government to local authorities do not always correspond to spending cuts because local authorities could avoid cutting spending by raising local taxes. Because in some countries, e.g. Italy, UK and Denmark, cuts in transfers have often been used, particularly in recent years, we have decided not to drop them but to include them among spending cuts, as reported in the original documents, following what Devries et al. (2011) did, probably for lack of information on the actions undertaken by local authorities. To the extent that local authorities have failed to cut spending and raised local taxes instead, this choice implies that we may have classified as EB a few plans which were really TB. If TB plans are more recessionary than EB plans, this mis-classification would make EB plans more recessionary. In the pre-2009 sample we have a total of 18 cases of such transfers. When we exclude them from the estimation sample the results are unchanged.

Figure 4. Fiscal consolidation examples

Notes: Impulse responses for tax-based (circles) and spending-based consolidations (squares). Numbers along the vertical axis report the cumulative effect on GDP per capita in percentage points.
using the estimated style of each country’s plans (the \( u_i; s \)). Different styles depend on the typical persistence of a shock, i.e. on the correlation between unexpected and anticipated shifts in fiscal variables within the average plan. For instance, in the case of Ireland, fiscal plans are typically purely unexpected and contain no announcements of future actions, while Italian plans are often reversed after 1 year.22

The results clearly show that fiscal consolidations implemented mainly by raising taxes entail large output costs.23 AFG show that the component of GDP which explains a large part of the difference between EB and TB adjustments is private investment.24 In the next sub-section we explore whether this feature of fiscal adjustments extends to the more recent period, i.e. to the adjustments implemented over 2009–13.

### 4.3.2. Output effects of fiscal austerity in 2009–13

#### 4.3.2.1. Effects of the plans adopted in 2009–13

The recent years offer an interesting opportunity to evaluate the predictions of our empirical model. There has been considerable variability across countries and across time in output growth during this period among the 11 countries in our sample. It is thus interesting to compare the model

---

22 Details about each country’s style of fiscal adjustment are provided in Table 5.

23 The impulse response functions in Figure 4 show the cumulated effects on GDP per capita.

24 AFG also find significant asymmetries in the responses of inflation and interest rates in the response to TB and EB plans. Differently, the responses of term spreads do not feature a significant asymmetry. This result is consistent with the evidence in Alesina and Ardagna (2010).
projection of output growth – conditional upon fiscal adjustment plans – with its observed path.

There are two questions we can attempt to answer: (i) How much of the recent recessions can be attributed to fiscal austerity and (ii) how much of the heterogeneity in the severity of the crisis across countries can be explained by the different styles of fiscal corrections. The reader should remember, however, that the tool we are using is not a forecasting model. Our model projects output growth conditional on fiscal shocks only, overlooking all other structural factors that have affected output growth in 2009–10. Overlooking such factors does not affect the validity of our estimates (as omitted variables are orthogonal to those included in the specification) but it certainly affects the ability of our model to track the observed output growth.

We compute out-of-sample simulations by feeding directly into our estimated model the actual plans adopted over the period 2009–13. We assess the effects of a fiscal consolidation comparing the simulated path of output growth, with the observed one. In Section 5.1, we shall discuss whether such an out-of-sample simulation is valid testing for a regime change between in sample estimates (up to 2007) and out-of-sample simulations (after 2009). The results are supportive of our counterfactual exercise.25

The results of our simulations are presented in Figures 5–7. On the left-hand side of each figure, we plot a histogram describing the size and composition of the fiscal adjustments happening in that year. Light grey columns represent years of TB consolidations, while spending-based years are coloured in dark grey. In each histogram we report the yearly impact (unexpected plus announced for time $t$) and the future announced shifts in fiscal variables, measured as a fraction of GDP. The impact is represented by the full-coloured columns, while announcements correspond to the cross-hatched columns of each figure. On the right-hand side panels we report:

- the actual GDP growth (in black);26
- the simulated GDP growth conditional on the implemented fiscal plan (line with stars, with 95% confidence intervals);
- what output growth would have been, according to the model, had the plan been totally EB (line with squared symbols);
- what output growth would have been, according to the model, had the plan been totally TB (line with circles).

In countries such as Germany, Spain, or the United States, where the plans actually implemented were almost totally EB, lines with stars and squares virtually coincide.

25 In principle the estimated model could have also been used to simulate the effect fiscal austerity in Greece over 2010–13. What stops us from doing this is that, as a consequence of the fact that Greece is not in the estimation sample, it is impossible to check that the adjustment over 2010–13 is not too different from those implemented in the past.

26 In the case of Ireland we also ran simulations for GNP, instead of GDP, and the results (available upon request) are essentially unchanged.
Figure 5. Benchmark and counterfactual simulation

Notes: Histograms on the left-hand side of the graph represent the planned fiscal consolidations in every year. Light grey columns represent years of TB consolidations, while spending-based ones are coloured in dark grey. In each histogram we report, the yearly impact ($e_t + e_{t0}$) and all the future announced shifts in fiscal variables, measured as a fraction of GDP. The impact is represented by the full-coloured columns, while the announcements correspond to the cross-hatched columns of each figure. On the right-hand side panels we report the corresponding simulated GDP growth (stars, with 95% confidence bounds) against the actual one (in black). Counterfactual GDP growth paths for totally tax and spending-based plans are, respectively symbolized by circles and squares.
Notes: Histograms on the left-hand side of the graph represent the planned fiscal consolidations in every year. Light grey columns represent years of TB consolidations, while spending-based ones are coloured in dark grey. In each histogram we report, the yearly impact ($e_t + e_{t+1}$) and all the future announced shifts in fiscal variables, measured as a fraction of GDP. The impact is represented by the full-coloured columns, while the announcements correspond to the cross-hatched columns of each figure. On the right-hand side panels we report the corresponding simulated GDP growth (stars, with 95% confidence bounds) against the actual one (in black). Counterfactual GDP growth paths for totally tax and spending-based plans are, respectively symbolized by circles and squares.
Our model matches the realized growth paths quite well, especially for those countries, such as Italy, where fiscal shocks were the main determinants of GDP growth. However, several caveats are in order.

First, as we already repeated a number of times, our model projects GDP growth only conditional upon fiscal consolidations. Therefore, we should expect a closer fit between actual and projected GDP growth in years during which there were no other significant shocks (e.g., economic, political, etc.). The evidence from 2012 and 2013 illustrates this point, as these years are more distant from the financial and economic

Figure 7. Benchmark and counterfactual simulation

Notes: Histograms on the left-hand side of the graph represent the planned fiscal consolidations in every year. Light grey columns represent years of TB consolidations, while spending-based ones are coloured in dark grey. In each histogram we report, the yearly impact ($e_t + e_{t,0}$) and all the future announced shifts in fiscal variables, measured as a fraction of GDP. The impact is represented by the full-coloured columns, while the announcements correspond to the cross-hatched columns of each figure. On the right-hand side panels we report the corresponding simulated GDP growth (stars, with 95% confidence bounds) against the actual one (in black). Counterfactual GDP growth paths for totally tax and spending-based plans are, respectively symbolized by circles and squares.

Our model matches the realized growth paths quite well, especially for those countries, such as Italy, where fiscal shocks were the main determinants of GDP growth. However, several caveats are in order.

First, as we already repeated a number of times, our model projects GDP growth only conditional upon fiscal consolidations. Therefore, we should expect a closer fit between actual and projected GDP growth in years during which there were no other significant shocks (e.g., economic, political, etc.). The evidence from 2012 and 2013 illustrates this point, as these years are more distant from the financial and economic
shocks of 2008 and 2009. There are also a few specific non-financial shocks that could explain why predictions do not match actual growth. The most relevant ones occurred in Portugal in 2010 and in Germany in the years closer to the crisis. For Portugal our predicted growth rate for 2010 is considerably lower than realized growth. One possible reason is stated in the EU Council Recommendation (with a view to bringing an end to the situation of an excessive government deficit in Portugal) (p. 5), which claims that in 2010 “positive growth of 1.4% was largely due to exceptional factors that boosted exports and private consumption”. In Germany, our projected growth rate is almost flat, which is distant from the growth rates realized right after the crisis. The IMF claimed that “the [German] uptick started in the second quarter of 2009, led by exports and aided by policy support and restocking of inventories”. Not surprisingly, the model cannot account for export-led growth. In general, given the features of our model, it is reasonable to expect a better fit in countries subject to impressive amounts of fiscal adjustment because these shocks were more likely to dominate other shocks.

Second, note that in some countries such as Ireland, Spain, and the United States, the model projections and the actual growth rate are set at different levels, especially when the fiscal adjustments are small. These are the countries where the average GDP growth before the crisis was significantly different (higher) from the one after the crisis. Remember that the model is estimated including a country fixed effect, which is the average GDP per capita growth over the years 1978–2007 (net of fiscal shocks) and represents a counterfactual growth in absence of fiscal shocks. Since the model simulations assume that fiscal policy affects GDP only relatively to the level of the fixed effect, this may lead to an overestimation of growth, especially when the fiscal adjustment is small, and for countries that in the post-crisis years could not catch up with their per-capita growth rates in the 80s and 90s.

Conversely, as shown in Table 6, the projected growth for Ireland, Italy, Portugal, and Spain show that the different nature of the fiscal adjustments contributes significantly in explaining growth differentials among these countries.

The results confirm that EB adjustments have been much less costly than TB ones.

Compare for example Ireland and Italy. The former had a draconian adjustment on the expenditure side and a small recession in 2010–3 after the disastrous banking collapse of 2009. Italy had a smaller adjustment but virtually all on the revenue side, at least up to 2013. The result (in Italy) was a deep recession, which is still ongoing. Portugal and Spain also feature a good match between observed output growth and that projected on the basis of predominantly EB fiscal adjustments. Note that in the case of Spain the bursting of the housing bubble contributed to the recession and high

\(^{28}\) “Germany: 2010 Article IV Consultation-Staff Report; Public Information Notice on the Executive Board Discussion; and Statement by the Executive Director for Germany”, p. 4.
unemployment above and beyond the effects of the fiscal adjustments. In fact, even though the Portuguese and Spanish governments implemented some of the largest consolidations of the whole sample, most of them were through spending cuts and the effect on GDP was low compared with the amount of deficit reduction implemented. The United Kingdom had a moderate EB adjustment and a small and short-lived recession. France had a moderate and mixed type of adjustment, and a moderate recession.

The size of the confidence bounds on our out-of-sample simulations differs across countries.29 There are two reasons for this. First, the uncertainty of the fixed effect, which captures the equilibrium rate of output growth in the absence of shocks, differs significantly across countries. Second, some plans may include elements (e.g. 2-year-ahead announcements) whose effects are less precisely estimated: This makes the uncertainty of the simulation dependent on the style of a plan. As a result in some cases, such as Italy, confidence intervals are relatively narrow; in others, such as Germany or Ireland, they are much larger. In the case of Italy the plans adopted over 2010–13 include components whose coefficients were precisely estimated. Moreover, Italy has a small standard error associated with its fixed effect. The German plans of 2010–13, instead, typically contained components (e.g. 2-year ahead announcements of a spending cut) not as precisely estimated and a high standard error on the fixed effect. In the case of Ireland, the significant size of each adjustment exacerbates the large standard error on the coefficients on unexpected EB shocks. Moreover, Ireland displays the largest standard error on the fixed effect among all countries in the sample.

29 Confidence bounds differ also compared with the impulse response functions presented in Section 4.3.1. The main reason is the inclusion of the country fixed effects uncertainty in the out-of-sample simulations. Second, impulse response analysis is based on the simulation of the average plan in which several adjustment plans are pooled together, while out-of-sample projections consider instead a specific plan.
4.3.2.2. Counterfactuals. Turning now to the counterfactual results (the lines with circles and squares, respectively, on the right-hand-side panels) notice that in countries such as Spain, Italy, Ireland, and Portugal, which implemented the largest fiscal consolidations (and where the model predictions best fit the actual growth), the nature of the fiscal plans plays a prominent role in determining the growth experience. For example, if Spain had implemented exactly the same adjustment but had chosen to mostly raise taxes, instead of cutting expenditures, its GDP growth would have been about 5% lower in 2013. On the other hand, had Italy chosen to mostly cut expenditures rather than raise taxes, its GDP growth would have been 2% higher in every single year since 2011, with a cumulative “additional” 6% points of growth.

Finally, notice that, as anticipated above, the model does not succeed in projecting growth in countries where the fiscal consolidation effort was small, since other shocks probably dominated. Hence in Germany or the United States, given the small magnitude of the adjustments implemented, it does not make a big difference whether the plans were predominantly TB or EB.

4.3.3. Robustness of the EB and TB dummy definitions

In the specification used so far fiscal shocks were interacted with the TB and EB dummies. As discussed above this specification may be sensitive to the categorization of plans into EB and TB. As a robustness check we run our model with a different specification in which we introduce $s$ and $g$ separately. That is we do not “label” fiscal adjustments as TB and EB but we simply use in the regressions the actual announced and unexpected tax hikes and spending cuts. We discussed above the pros and cons and this approach relative to our previous specification based on a classification of plans in EB and TB. One advantage of this approach is to avoid potential mis-specifications in cases where the allocation of spending cuts and tax increases is close to fifty–fifty – a case, as we discussed above, that almost never happens in our samples. This alternative specification is

$$
\Delta y_{i,t} = \alpha + B_1(L)\tau_{i,t} + B_2(L)\tau_{i,t,0} + C_1(L)g_{i,t} + C_2(L)g_{i,t,0} + \sum_{j=1}^{3} \gamma_j \tau_{i,t,j} + \sum_{j=1}^{3} \delta_j g_{i,t,j} + \lambda_i + \chi_i + \mu_{i,t}.
$$

The estimated coefficients are shown in Table 7 and are qualitatively very similar to the ones obtained with the benchmark model. The coefficients on taxes, when significant, are all negative, the coefficient on spending, when significant (which happens only marginally for one of them) are positive. Note however that inferring the response of output growth to taxes and expenditure from these coefficients only is warranted in the case tax and expenditure adjustments are orthogonal to each other, a condition that it not usually satisfied. Figures 8–10 reproduce, using the new specification, the results shown in Figures 5–7. The new results are consistent with those obtained using the EB/
TB dummies. For some countries, such as Spain and Portugal, the model above delivers projections closer to realized GDP growth than those in our baseline specification.

5. WERE THE RECENT FISCAL ADJUSTMENTS ESPECIALLY COSTLY?

The recent episodes of austerity happened under special conditions. They followed the Great Recession (in fact they started during its tail end) and the financial crisis, which led to credit crunches. In most cases, market conditions forced European countries to start deficit reduction policies when the recession was not yet over and financial markets were still experiencing a credit crunch. In addition, many countries implemented fiscal contractions at the same time. All of these factors might suggest that the recent fiscal consolidations might have been more costly than those of previous decades.  

30 Blanchard and Leigh (2013a) argue that this was indeed the case. We investigate their finding that, in the recent round of fiscal adjustments, fiscal multipliers were larger than anticipated and we find that the evidence in favour of a change in fiscal multipliers is very weak.

In addressing this question it is important to distinguish between two possibilities. One is that fiscal multipliers were larger in these recent rounds of fiscal adjustments than

* $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$. 

All of these factors were outlined (among others) by Christiano et al. (2011), Eggertsson and Krugman (2012), Auerbach and Gorodnichenko (2012), OECD (2014b).
Figure 8. Model simulation after direct estimation of $\tau$ and $g$, separately

Notes: Histograms on the left-hand side of the graph represent the total impact of fiscal consolidations in every year. Dark grey columns represent spending measures, while tax measures are in light grey. In each histogram we report, the yearly impact $(\epsilon_{t}^{\tau} + \epsilon_{t}^{g})$ and all the future announced shifts in fiscal variables, measured as a fraction of GDP. The impact is represented by the full-coloured columns, while the announcements correspond to the cross-hatched columns of each figure. The right-hand side of the graph plots the simulated growth (stars), with 95% confidence bounds, against the actual growth (black). The model used to simulate plans employs spending and tax shocks separately. No tax and spending-based dummies are included.
Figure 9. Model simulation after direct estimation of $\tau$ and $g$

Notes: Histograms on the left-hand side of the graph represent the total impact of fiscal consolidations in every year. Dark grey columns represent spending measures, while tax measures are in light grey. In each histogram we report, the yearly impact ($r_t + c_t^e$) and all the future announced shifts in fiscal variables, measured as a fraction of GDP. The impact is represented by the full-coloured columns, while the announcements correspond to the cross-hatched columns of each figure. The right-hand side of the graph plots the simulated growth (stars), with 95% confidence bounds, against the actual growth (black). The model used to simulate plans employs spending and tax shocks separately. No tax and spending-based dummies are included.
estimated using pre-crisis data: This is the question asked by Blanchard and Leigh (2013a). The other is that fiscal multipliers were not different but additional shocks (like credit crunches for instance) created deep recessions regardless of the size of fiscal multipliers. Within the framework of this paper we can only investigate the first of these questions.

We begin by testing whether our model implies a regime change between in-sample estimates (up to 2007) and out-of-sample simulations, after 2009.
5.1. Testing for a regime change

5.1.1. Test on joint equality of coefficients

We first test for the joint stability of our parameter estimates between the two samples 1981–2007 and 2008–2013. In order to run the test we interact each of the 20 coefficients measuring the output effects of shifts in fiscal variables with a time dummy taking the value of 1 after 2008.\textsuperscript{31} The joint significance of each of these stability parameters is evaluated using the Wald test.

The hypothesis of structural stability is not rejected with alpha = 0.01 but rejected with alpha = 0.05. Hence, we are at the margin of structural instability. However, the Wald test for the joint significance of so many parameters could be driven by transitory movement in just a single parameter. This is indeed the case since when we drop the coefficient for $e_{t-3,0}$ from the test we do not reject stability even with alpha = 0.1. As a consequence, we consider the estimates obtained using pre-crisis data to give valuable information about the amount of output loss due to the post-crisis fiscal consolidation measures. An additional caveat is that we are looking at a structural break rather close to the end of the sample, thus with very few observations after the break, which makes the test less precise.

5.1.2. Changing the estimation sample

To further support this point, we next provide a visual comparison (with confidence intervals) between the simulations produced using parameters estimated in the two samples: 1981–2007 and 1981–2013.

To do this, we re-estimate our model over the extended sample (1981–2013) and we then use the new estimated coefficients to simulate GDP growth inputting post-crisis shocks. Figure 11 plots the predicted growth rates using the new estimates (squares) against those computed in the previous section (Figures 5–7) (stars). The new projections track actual GDP growth closer, as expected, but they do not differ significantly from those based on within-sample estimation.

5.2. Did fiscal multipliers change after the crisis?

\textbf{Blanchard and Leigh (2013a, hereafter BL)} address the stability of fiscal multipliers using a different approach. They investigate the relation between the IMF growth forecast errors and the total amount of fiscal consolidations expected to be implemented in 2011, based on IMF forecasts. In practice, they run an OLS regression on a cross-section of 27 advanced economies employing a cyclically adjusted measure of changes in the structural budget balance. They find that 'stronger planned fiscal consolidation has been

\textsuperscript{31} Our test can be thought of as a version of the Chow Test that allows for the presence of country fixed effects in the panel data.
associated with lower growth than expected, with the relation being particularly strong, both statistically and economically, early in the crisis. Their results suggest that for every additional percentage point of GDP of fiscal consolidation, GDP was about 1% lower than forecasted. They interpret the result as implying that fiscal multipliers in 2011 were higher than those predicted by forecasters.32

In order to assess this evidence it is important to realize that the forecast errors constructed in BL are conditional upon a scenario for all the exogenous variables that enter the IMF forecasting model. Their forecast errors could therefore reflect surprises in such scenario and in the response of all endogenous variables to such surprises. Our approach instead delivers a projection of GDP growth conditional only on the fiscal adjustment. As a consequence, a regression of the residuals of our model – produced by projecting

---

32 BL investigate the robustness of their results replacing IMF forecasts with those of other forecasters: the EC, the OECD, and the EIU. They find that their results are robust. These alternative forecast, however, suffer of the same weakness we have pointed out for IMF forecasts.
GDP growth only on the announced fiscal adjustment – run on the fiscal adjustment itself, can provide more direct evidence on the potential structural instability of fiscal multipliers.

To illustrate this point, we run the following regression:

\[ D_y_{it} + i/C_{0,E} D_y_{it} + i/j e_{it};; TB_t; EB_t/C_{8,C9} = a + b e_{it} + e_{it}: \]

The dependent variable is the discrepancy between the actual growth rate and the growth rate projected by our model, and \( e_{it} \) is the narrative measure of the deficit-driven fiscal consolidation actions (unexpected and announced). The model projections allow for a different impact on growth of TB and EB plans, therefore the nature of the plan is an important element of the conditioning information set.

If fiscal multipliers are stable, the estimated coefficient linking the real growth projection error and our narrative measure of fiscal episodes \((\beta)\) should be centred on zero.

Notice the difference with the BL specification. In the BL specification the forecast error is the difference between realized growth and growth as predicted by the IMF forecasting model thus is conditional on all the exogenous variables forming the scenario of such model, not only fiscal variables, moreover no difference between TB and EB plans is allowed in this specification.

We first estimate the model using OLS and restricting the sample to the cumulated forecast errors in 2010–11, in order to exactly replicate BL. Results are reported in Table 8. The estimate of \( \beta \) (0.243) is small, not significantly different from zero, and about one-third of the value estimated in BL. Extending the estimation period to include the observations in 2010–13 the magnitude of the estimated coefficient does not change but is now significant at the 1% level (Column 2). In other words, for each additional percentage point of fiscal consolidation after the financial crisis, GDP turned out to be 0.4% lower than accounted by our model, a value only marginally significant. However, introducing country-fixed effects the coefficient becomes again insignificant while not changing in magnitude (Column 3). Results are robust to the inclusion of the sum of fiscal announcements in the specification (Column 4). Summing up, our results suggest,
differently from BL, that probably only minor or no changes in the fiscal multiplier have occurred after the crisis.

The difference of our results with respect to the ones in BL might be due to many factors. First, as we said, our structural break test uses a model conditional only on fiscal policy with heterogeneous effect of EB and TB plans, and not conditional on the whole information set of IMF forecasters. Second, if the composition of the fiscal adjustments post-2010 differed from the average composition in the past, this could explain why models that impose identical effects of TB and EB adjustments, such as the IMF forecasts, find a break in the estimated multiplier. Finally, there are fewer countries in our sample, compared with that of BL.

6. CONCLUSIONS

The conventional wisdom is first that fiscal austerity was the main culprit for the recessions experienced by many countries, especially in Europe and, second, that this round of fiscal consolidation was much more costly than the past ones. The contribution of this paper is a clarification of the first point and, if not a clear rejection, at least it raises doubts on the second.

On the first point our main finding is that, as in the past, in the recent episodes there has been a very big difference between TB and EB fiscal adjustments. The former have indeed been very costly in terms of output losses. The latter much less so. These results are very similar to those obtained by many authors who have studied the effects of fiscal adjustments preceding the period 2010–13. Comparing our results on these recent adjustments and the ones obtained using pre-crisis data – that is up to 2007 – we did not find strong evidence against the hypothesis that fiscal multipliers – large tax multipliers and very small spending multipliers – were stable across the two sub-samples.

Our results, however, are mute on the question whether the countries we have studied did the right thing implementing fiscal austerity at the time they did, that is 2009–13. Consolidations, as illustrated in Figure 2 at the beginning of the paper, all happened at the trough of a recession, which normally is not a good time to adopt fiscal restraint. However, the surge in interest rates on public debt on the European periphery might have fuelled dangerous debt crisis. In some countries, such as Spain, Ireland, and Portugal, fiscal consolidations have been accompanied, at least in 2012–13, by other (non-fiscal) shocks to the economy that have depressed output growth, raising

33 To investigate whether their baseline results are driven primarily by spending cuts or by revenue increases, BL split their measure of fiscal consolidation – the change in the cyclically adjusted fiscal balance – into the change in government spending and revenue and estimate the model separating between the change in spending and the change in revenue. They find that overall fiscal multipliers were, on average, underestimated for both sides of the fiscal balance, with a slightly larger degree of understimation associated with changes in government spending. Once again, however, it is impossible to separate, within this framework, between overall forecast errors and forecast errors signalling a change in fiscal multipliers.
the question of whether the intensity of the fiscal contraction was “optimal”. This is an important question, but one that, within the framework adopted in this paper, we cannot answer. We would need a structural model capable of tracking the effect of several shocks.

In order to obtain these results we constructed a detailed “narrative” dataset that documents the actual size and composition of the fiscal plans of several countries in the period 2009–13. The plans are composed of preannounced and unexpected policy changes often with many revisions in mid-course, which incidentally added much uncertainty in expectations, an uncertainty that may have had negative effects on investments. Thus, an additional contribution of this paper is a clarification of these complex dynamic evolutions and the construction of a new narrative dataset on recent fiscal adjustments. We have then estimated the output effects of these fiscal plans simulating out-of-sample a model that allows for anticipated and unanticipated shifts in fiscal variables, as well as for differences in the response of output to tax and spending changes.

Two criticisms could be raised to our analysis. First, our out-of-sample simulations are constructed under the assumption that fiscal multipliers did not change during the financial crisis, when monetary policy hit the zero lower bound. When we test explicitly the hypothesis that recent fiscal adjustments had the same effect on output growth as past ones, we find it hard to reject the null, although in some cases failure to reject is marginal. This result appears inconsistent with some recent empirical findings (discussed in the paper) where the costs of fiscal adjustments are found to be higher in recent years. One reason for this difference is the assumption – made in most studies of fiscal multipliers, but relaxed in this paper – that tax and spending multipliers are identical, and thus that one can estimate the output effects of “a fiscal consolidation”. If, as the data strongly suggest, fiscal multipliers depend on the composition of a fiscal correction, imposing that the effects of TB and spending-based consolidations are identical will result in distorted estimates of the multiplier. Such distortion will depend on the composition of the average fiscal adjustment which occurred over the estimation sample. If the composition of the fiscal adjustments post-2007 differed from the average composition in the past, this could explain why models that impose identical effects of TB and spending-based consolidations find a break in the estimated multiplier.

The second, and in this case warranted, criticism is our failure to consider accompanying policies and to ask whether countries that accompanied fiscal austerity with structural reforms experienced better output growth than countries which did not. As noted in the Introduction section, and as documented in Alesina and Ardagna (2010, 2013) and Perotti (2013), multi-year fiscal adjustments rarely occur in isolation. They are often accompanied by other policies (a devaluation, a labour market reform or a pension reform) and their effects will vary depending on these policies. These policy packages have in the past delivered cases of “expansionary fiscal consolidations” in which countries have managed to avoid any recessionary cost of fiscal contractions. In the current rounds of adjustments, except for the few pension reforms which we documented (with benefits accruing with several years of delay) and of the Spanish labour market reform, the fiscal corrections
of 2010–13 were mostly implemented in a rush under market pressure and governments rarely had the time to design and get Parliaments to approve significant reforms. For instance, only in 2014 did Italy implement a major labour market reform in the context of a pro-growth medium term package. More research is warranted on this point.

**Discussion**

Gernot Müller  
Eberhard-Karls-University Tübingen

Austerity is frequently blamed for the post-2009 slump in the euro area. The basis for this judgement is weak: Many observers and voters are apparently ready to jump from jointly observing poor economic outcomes and austerity to the conclusion that austerity is indeed the cause (see, for instance, Blyth, 2013). The present paper proposes a methodologically refined approach in order to explore the issue rigorously and thus makes a most welcome contribution to the debate.

Two findings stand out. First, tax-based fiscal consolidations are much more costly in terms of output growth than spending-based consolidations – in line with the earlier results established by some of the authors of the current study. In fact, spending-based consolidations seem to affect output hardly at all. Second, the recent consolidation effort has not been any more costly than earlier fiscal consolidations. This finding goes against the popular notion that fiscal multipliers have been particularly high during the recent crisis.

In my discussion I take up three points which concern both methodological and material aspects of the analysis. First, I explain why in the present context applying the narrative approach to identification is less compelling than it may appear at first sight. Second, I argue that the framework used in the paper is not fully suited to capture the state-dependence of fiscal multipliers and, hence, to address the issue of how costly the recent consolidation effort has been. Third, I interpret the empirical results through the lens of a New Keynesian small open economy model.

Empirical studies of the fiscal transmission mechanism cannot avoid making controversial assumptions in order to achieve identification. The current paper is no exception. Box 1 contrasts the narrative approach used in the paper and the VAR approach. The authors argue that because of fiscal foresight the VAR approach has “become less successful” recently: If fiscal policy measures are anticipated, it is difficult to back out structural shocks from VAR innovations. This argument is by now well understood and conceptually compelling. It features prominently in the debate on fiscal VARs (Ramey, 2011; Leeper et al., 2013). Its quantitative relevance, however, is unclear, because controlling for anticipation often has no perceptible effect on the results (see, e.g., Corsetti et al., 2012a; Born et al., 2013).

The narrative approach, on the other hand, is not without shortcomings either. Recall that it seeks to identify tax and expenditure changes that are not correlated with the business cycle. This is achieved through a close reading of the policy process. Specifically, in the present study the authors select as exogenous shocks those fiscal measures which are designed to deal with inherited budget deficits (rather than the cycle). My concern with this approach is simple, but fundamental: The budget deficit, or more generally the fiscal outlook of a country is likely to correlate with the business cycle, at least if public finances are strained (see, e.g., Reinhart and Rogoff, 2010; Corsetti et al 2013). As the latter proviso is clearly met for several countries in the sample, the identification assumption is violated: The narratively identified fiscal shocks are not orthogonal to the cycle. I thus remain unconvinced of the arguments on which the present paper’s empirical strategy is based.

I now turn to the question of whether fiscal multipliers changed after the crisis, a hypothesis popularized by Blanchard and Leigh (2013b). The underlying idea is that (i) fiscal multipliers depend on the state of the economy and that (ii) the macroeconomic environment has changed fundamentally after 2009. Still, the present paper rejects the hypothesis of a change on the ground that it finds no significant effect of fiscal shocks on the forecast errors for output growth. The setup of the test differs from Blanchard and Leigh only in that it conditions the forecast errors on fiscal shocks.

Yet it is unclear whether this setup is generally suited to address the question of whether “fiscal multipliers changed after the crisis.” In Corsetti et al. (2012b) we ask “What Determines Government Spending Multipliers?” For a sample of 17 OECD countries we document that spending multipliers change depending on (i) the exchange rate regime, (ii) the health of public finances, and (iii) whether there is a financial crisis or not. Importantly, relative to a baseline scenario (of flexible exchange rates, fiscally and financially benign times), the multiplier changes in different ways, depending on which dimension is considered. Altering the exchange rate regime from float to peg raises the multiplier. The multiplier also increases during times of financial crisis, but declines in times of fiscal stress relative to the baseline.

The crisis has certainly changed the macroeconomic environment, but each unhappy country is unhappy in its own way: While some countries suffer primarily from a financial distress (e.g. Spain), others rather suffer from fiscal stress (e.g. Greece). As variations along those dimensions impact government spending multipliers differently, the average multiplier may not have changed in a cross-section of countries – even if it changed strongly within individual countries. The recent austerity packages are therefore likely to affect countries quite differently from earlier ones – more adversely in some instances, less so in others. Considering the average change in the multiplier within a large sample of countries is therefore of little help to assess the issue.

Recall that a major innovation of the paper is to assess the growth effects of multi-year fiscal plans rather than one-time fiscal measures. This approach permits capturing the effects not only of contemporaneous austerity measures, but also of those which are anticipated to be implemented in the near future. While the authors make a
considerable and quite convincing effort to argue that accounting for fiscal plans is important, there is no systematic assessment of whether results do indeed depend on this methodological innovation.

In what follows I rely on model simulations to explore the issue. Specifically, I consider a standard New Keynesian small open economy which operates with in a currency union (or, equivalently, maintains an exchange rate peg). I study the dynamic adjustment of selected variables to (i) a permanent spending cut and (ii) a permanent tax hike and distinguish, in both instances, the case where the measure takes effect immediately and the case where the measure is known to take effect four quarters down the road. A time period in the model simulation is assumed to be one quarter, parameters values are standard (see, e.g., Born et al., 2013, for an exposition of the model).

Results are shown in the figure. The top row shows the adjustment to a cut of government expenditure by 1% of GDP (from 20% to 19% of total output), the bottom row shows the dynamics triggered by an increase of the income tax rate by one percentage point (from 20% to 21%). Dashed (solid) lines show results under the assumption that consolidation takes place immediately (after four quarters only). Horizontal axes measure time in quarters. Vertical axes measure the deviation from the pre-shock level in percentage points.

Two observations are noteworthy. First, both spending cuts and tax increases are contractionary if they take effect immediately. This result is well understood. Consider government spending cuts: As inflation declines with public demand, real interest rates decline (nominal rates are unchanged as the economy is small) such that private expenditure is crowded in, partially offsetting the decline in public expenditure.
The crowding-in effect is moderate, however, and the multiplier on output is positive, that is, economic activity declines with government spending, albeit not one-for-one. As for tax cuts, there is no direct effect on aggregate demand. However, taxes are inflationary, pushing up real interest rates. This, in turn, crowds out private expenditure and overall economic activity again declines with aggregate demand.

Second, the announcement effect of anticipated fiscal measures differs for spending cuts and tax hikes. Anticipated spending cuts are expansionary – an effect analysed in detail in Corsetti et al. (2012b). Intuitively, with forward-looking price setting in the New Keynesian framework, prices decline prior to the spending cut. Real interest rates decline and private demand expands. The opposite holds for anticipated tax hikes.

Given these results, there is a natural interpretation of the empirical results of the paper. After all, the growth effect of a multi-year plan is the joint effect of current measures and the announcement effect of anticipated measures. Hence, spending-based plans may be less detrimental to economic activity, because the adverse growth effect of the immediate measures is (partly) offset by the growth-friendly announcement effect of the anticipated spending cuts. Tax-based plans, instead, are very detrimental to economic activity, because both the immediate effect and the announcement effect crowd out private expenditure.

The model simulations, however, also suggest that the growth friendly effect of anticipated expenditure cuts is (partly) undone, once the spending cuts actually materialize. This finding warns against too much optimism regarding the growth effects of spending-based adjustments. It may well be that – upon announcement – a spending-based fiscal adjustment is less harmful to growth. Yet the growth effect may be even more negative, once the plan is realized.

Alan M. Taylor

University of California, Davis

With Europe mired in a terrible, long slump, it is hardly surprising that the ongoing debate over the austerity policies implemented during the Great Recession remains very active. Given that arguments over macroeconomic policy choices in the 1930s are contentious to this day, I have no doubt that we will be engaged in this discussion for a very long time to come.

To recap the basic details, this has been the worst recession in 75 years in the advanced economies as a whole. In some countries and regions the downturn has dragged on to make it the worst in over a century, where output gaps or deviations from pre-crisis growth trends are considered. For example, in the United States, United Kingdom, and Eurozone, the 2014 deviations from 10-year pre-trends of real GDP are currently in the range 12%–18%, and OECD data indicate output gaps are about 5% or 6% of GDP, even taking their quite pessimistic view of the structural loss in potential.
While we know that financial crisis recessions, and especially highly leveraged ones like this, are typically worse than normal recessions (Jordà et al., 2013), even these historical tendencies, when projected onto current data, fail to fully account for the truly dismal economic performance we have seen, especially in case of the United Kingdom and the Eurozone. Understandably, then, attention is led towards another possible cause of slow recovery, namely policy choices.

This generation of economic policymakers will eventually be held to account by future economic historians. Will their policy choices be judged as harshly as their 1930s predecessors’ rigid adherence to gold standard ideology and balanced-budget orthodoxy in the dark days of the Great Depression? Only time will tell, but a slew of research in the last few years will shape those answers and this paper makes a signal contribution.

A striking aspect of this paper is that it essentially resolves, and moves us beyond, the tired “expansionary austerity” debate. In that debate, one side presented findings of expansionary fiscal contraction; this unusual idea was associated primarily with the influential work of Alesina and Ardagna (2010), but it built on earlier ideas going back many years (Giavazzi and Pagano, 1990; Alesina and Perotti, 1995). Pushback on the other side of the argument was seen in the widely cited work of Guajardo et al. (2014), and in other policy analyses from the IMF’s Research Department (e.g. Blanchard and Leigh, 2013).

It is clear which side of this argument prevailed in the policy world in 2010–3: the shift to austerity in the advanced economies was large and pro-cyclical, especially in the Eurozone and United Kingdom (Figure 2 in this paper). In these policy choices, politics may have been one of the drivers, e.g. the desire to shift to a smaller state. However, to the extent that an intellectual argument based on macroeconomic research was offered, the claims for expansionary austerity were one part of the story.34

I think it is fair to say that, by now, the expansionary austerity view has been undermined not only by the outturn of events but also by new research. In addition to the research by the IMF and others on general historical patterns, the “Austerity Myth” paper by Perotti (2013) also explained why in current circumstances the policies of austerity might be more damaging than in the past, not least because the downturn was synchronized in many countries, so the export route to recovery was choked off, and there was less scope (and intra-Eurozone, none at all) for any country-specific stimulus via currency depreciation.

As the data of Guajardo et al. (2014) show, fiscal consolidation events are a mix of tax and spending measures. Each of these types of policies can have its own particular “multiplier” (or over many years, impulse response or dynamic multiplier) associated with it. One could not possibly identify in observable data the multiplier for every

---

34 Although so too was a concern that high debt levels might impair economic growth prospects, with the work of Reinhart and Rogoff (2010) being influential.
different kind of fiscal shock, so the first step was to find the “average treatment effect” as it were, which the first papers in the literature sought to do, as in earlier work including Alesina and Ardagna (2010). On average GLP found large positive fiscal multipliers, i.e. strongly contractionary austerity, contra the findings in AA. Using techniques to address the endogeneity of fiscal consolidation events, even stronger contractionary austerity patterns were found by Jordà and Taylor (2013).

In light of this recent history of thought it is, I think, striking that this new paper by Alesina et al. comes down firmly in agreement with the GLP and Jordà–Taylor view, with evidence here that strongly rejects the expansionary austerity view. Why so? If we look at Figure 4, and if we take the average of the tax and spend multipliers, the path would be significantly negative, rising to around $-1\%$ as we go out four years.

The attentive reader might thus conclude that the case for expansionary austerity is now effectively over, although this paper could perhaps have made its endorsement of this consensus a bit more explicit. And indeed this conclusion squares with an eyeball correlation from the headline data in Table 3. As is well known, in order of recovery speed after 2009, the United States did better than the United Kingdom, and Eurozone growth was worst of all, especially if one excludes Germany. The inverse ordering can be seen for their austerity programmes: mild consolidation in the United States, aggressive in the United Kingdom, and extreme in non-German-speaking parts of the Eurozone.

But as is also obvious from the same figure, the authors have shifted us on to new ground and another very important question. Is there a difference between the tax and spending multipliers? With these new goal posts a new sub-debate over the impacts of different kinds of austerity will surely trigger fresh research and that will be very welcome. And already differences in views are apparent. The IMF team, using a different estimation strategy, has found arrived at slightly different impacts and inferences (Guajardo et al., 2014); they speculate that the differences have as much to do with different monetary policy responses as to the possibility of asymmetric fiscal multipliers per se.

How will this debate play out? The importance of this paper is that, like Alesina and Ardagna (2010), it will set a reference point for further work, along with its closely related companion paper (Alesina et al., 2015). What will future researchers look at? I would highlight three points that seem likely to attract attention.

First, skeptics will ask if the data construction and estimation strategy is sound, and if it is possible within this very complicated decomposition method to extract the timing and anticipation effects of policy. Is the data plausible and are the inferences therefore robust to the coding? As we have seen from the earlier rounds of debate, moving from one measure to another (e.g. from attempts to use inferred changes in CAPB versus the narrative approach) differences in data construction methods can be very influential for the final result. The timing decomposition here is highly original (a thing always to be welcomed in research) but not yet widely tested and replicated by others (which will surely come later).
Second, skeptics of an econometric bent will wonder if the standard errors can be believed. The authors have faced this question many times, and the tightness of some of the error bands on tax responses in, say, Figure 4 is impressive, especially given the small sample size. Previous studies have typically found wider bands, even when using only one type of consolidation indicator bin, not two. Smaller sample sizes in each bin usually widen confidence intervals, but not here. I predict that one focus of future work will be to exhaustively check this aspect of the findings.

Thirdly, on model specification, do we need to do more to address the possible endogeneity of the policy actions and do we need to worry about state-contingent multipliers? In Jordà and Taylor (2013) both issues were addressed: the IMF’s indicator of a fiscal action, a purported narrative instrument, was found to be predictable and we may need to think about whether such techniques can be applied to tax and spend policy choices separately. In addition, JT found that fiscal multipliers were much larger in slumps (i.e. when output is below trend). However, if this paper or future papers try to go in this direction the problem of small sample size will start to bite, as we slice up episodes into tax-spend and boom-slump bins, we will end up with worryingly small sample sizes in each bin.

By way of conclusion, I will also highlight a key “out of sample” empirical puzzle raised by the paper for the current period, one which may be of as much interest to policymakers as to academics.

As is clear from Table 3 here, most of the fiscal consolidations in 2009–13 have taken the form of spending-based not tax-based programmes. With the exception of Italy (29%), a country close to each author’s heart—and to mine also—most countries have instituted austerity programmes that are between 60% and 100% expenditure based. For example, according to these data, UK Chancellor George Osborne pursued a programme 100% based on expenditure cuts.

However, if the main message of the paper is that fiscal consolidation based on spending cuts is going to be more successful, skeptics will then ask: why has the outturn still been so bad? In the United Kingdom, for example, the recovery was the slowest in 100 years—worse than the 1930s—and arguably the worst in 300 years (Thomas et al., 2014); yet the Chancellor followed the plan suggested by this paper and slashed spending. For a second example, consider Italy versus Spain. With its fiscal consolidation dominated by taxes, Italy’s economic performance ought to have been much worse in the window of analysis, ceteris paribus; yet the reverse obtained, and from 2009 Q1 to 2013 Q4 the official data on real GDP show output contracting by 2% in Italy but by 4% in Spain.

If it were true, as Figure 4 suggests, that spending-based consolidations are virtually painless, then the mysterious underperformance of most of the advanced economies pursuing this policy since 2009, even relative to the historical record of major financial crisis disasters, would have to be seen as even more of a puzzle. More research is needed to close this gap in our understanding, and this provocative paper certainly offers further motivation for the study of austerity and its impacts.
Panel Discussion

Eugenio Gaiotti wondered what policy conclusions the authors draw from the result that there is no evidence of the instability of the multiplier. He thought that the results of the paper suggested the recession was dull at least in some countries, which was exactly what the IMF story had been trying to demonstrate. He also pointed out that the choice between expenditure-based and tax-based adjustment might be endogenous, which may bias the authors’ results.

Tommaso Monacelli drew attention to the connection between the paper presented and the paper by Martin and Philippon (2014) that relates the heterogeneity in recessions in Europe to household debt and fiscal policy. Martin and Philippon (2014) showed that the cross-country variation in leverage is mostly responsible to heterogeneity, and they attribute a smaller role to fiscal consolidation. He also asked how concerned the authors are about the nonlinearity of the effects of fiscal policy. He pointed out that the concern about nonlinearity seems to be a serious problem here because the authors are using the coefficients estimated at normal times from a linear model for out-of-sample forecast into a major recession.

Commenting on Alan Taylor’s discussion, Favero told that it would be interesting to bring together the analysis of tax-based and expenditure-based adjustment with the different cyclical effects of fiscal adjustment. Although he agreed that it is important to allow for different nonlinearities, he thought that this might lead to econometric problems due to the increased number of parameters to be estimated. He further clarified that they did not use the IMF shocks that add the implemented part to the unanticipated part, creating predictability. Favero also pointed out that the model presented was not a structural model but was designed to gather evidence that a structural model should mimic. Hence, one should not draw policy implications from this empirical model.

SUPPLEMENTARY DATA

Supplementary data are available at Economic Policy online.

APPENDIX 1: PLANS AND THE MEASUREMENT OF THEIR EFFECTS OF OUTPUT

The fiscal plans studied in the paper are constructed expanding the data put together, using the narrative method, by Devries et al. (2011). Jordà and Taylor (2013) have argued that the episodes of fiscal consolidation identified by Devries et al. (hereafter referred to as “IMF corrections”) are not exogenous, and thus are not valid instruments
because they can be predicted using their own past (strongly), past values of output growth (very weakly), and past values of debt dynamics (weakly).

Some discussion of this point is in order. Consider our description of fiscal adjustment plans:

\[ f_{i,t} = \epsilon_{i,t}^\alpha + \epsilon_{i,t,0} + \epsilon_{i,t,1} \]

\[ \epsilon_{i,t,1} = \varphi_{1,i} \epsilon_{i,t}^\alpha + \epsilon_{1,i,t} \]

\[ \epsilon_{i,t+1,0} = \epsilon_{i,t,1} \]

\[ f_{i,t}, \] the narrative exogenous fiscal adjustment in each year, includes three components: The unexpected adjustments (announced upon implementation at time \( t \)), the past announced adjustments (implemented at time \( t \) but announced in the previous years), and the future announced corrections (considering, for simplicity, the case in which the horizon of the plan is only one year these corrections are announced at time \( t \) for implementation at time \( t + 1 \)).

The IMF corrections are defined as follows \( \epsilon_{i,t}^{\text{IMF}} = \epsilon_{i,t}^\alpha + \epsilon_{i,t,0}^{\text{IMF}} \). Based on this definition, the fact that \( \epsilon_{i,t}^{\text{IMF}} \) are correlated across time is not surprising. In fact, if fiscal policy is implemented through plans, \( \epsilon_{i,t}^{\text{IMF}} \) are correlated by construction

\[ \text{Cov}(\epsilon_{i,t}^{\text{IMF}}, \epsilon_{i,t-1}^{\text{IMF}}) = \text{Cov}(\epsilon_{i,t}^\alpha + \epsilon_{i,t,0}^{\text{IMF}}, \epsilon_{i,t-1}^\alpha + \epsilon_{i,t-1,0}^{\text{IMF}}) = \varphi_{1,i} \text{Var}(\epsilon_{i,t-1}^\alpha). \]

When plans are considered initial shocks are given to \( \epsilon_{i,t}^\alpha \), rather than to \( \epsilon_{i,t}^{\text{IMF}} \), and \( \epsilon_{i,t}^\alpha \) differently from \( \epsilon_{i,t}^{\text{IMF}} \), are not predictable from their own past.

Given an initial shock to \( \epsilon_{i,t}^\alpha \), the effects of a fiscal plan are simulated using a moving average representation of output growth that projects it on each of the three types of fiscal action, supplemented by the set of equations describing the country-specific style of the plan

\[ \Delta y_{i,t} = \alpha + B_1(L) \epsilon_{i,t}^\alpha \ast TB_{i,t} + B_2(L) \epsilon_{i,t,0}^\alpha \ast TB_{i,t} + C_1(L) \epsilon_{i,t}^\alpha \ast EB_{i,t} + C_2(L) \epsilon_{i,t,0}^\alpha \ast EB_{i,t} + \sum_{j=1}^{3} \gamma_j \epsilon_{i,t,j}^\alpha \ast TB_{i,t} + \sum_{j=1}^{3} \delta_j \epsilon_{i,t,j}^\alpha \ast EB_{i,t} + \lambda_i + \chi_i + \mu_{i,t}. \]

\[ \epsilon_{i,t,j} = \varphi_{i,j} \epsilon_{i,t,j}^{\text{IMF}} + v_{i,t,j} \quad j = 1, 2, 3 \]

\[ \epsilon_{i,t,0} = \epsilon_{i,t-1,1} \]

\[ \epsilon_{i,t,j} = \epsilon_{i,t-1,j+1} + (\epsilon_{i,t,j} - \epsilon_{i,t-1,j+1}) \quad j > 1 \]

Importantly \( \epsilon_{i,t}^\alpha \) are not predictable by their own past and are not correlated with the cycle. But since \( \epsilon_{i,t}^\alpha \) are identified via the narrative method – selecting adjustments designed to offset the expansionary changes in government spending occurred in the past – they are predictable by past changes in government debt.
Exogeneity, however, is different from predictability. Consider, for the sake of illustration, this simple representation

$$\Delta y_{t,i} = \alpha + \beta \epsilon^u_{i,t} + \mu_{1,t}$$

$$\epsilon^u_{i,t} = \rho \epsilon^u_{i,t-1} + \mu_{2,t}$$

$$\begin{bmatrix} \mu_{1,t} \\ \mu_{2,t} \end{bmatrix} \sim N \begin{pmatrix} 0 \\ 0 \end{pmatrix}, \begin{pmatrix} \sigma_{1,1} & \sigma_{1,2} \\ \sigma_{2,1} & \sigma_{2,2} \end{pmatrix}$$

The condition required for $\epsilon^u_{i,t}$ to be weakly exogenous for the estimation of $\beta$ is $\sigma_{1,2} = 0$, which is independent from $\rho = 0$: When $\sigma_{1,2} = 0$ and $\rho$ is different from zero $\epsilon^u_{i,t}$ is predictable but exogenous for the estimation of the parameter of interest $\beta$.

To sum up, our methodology is based on a truncated MA representation where plans take care of most of the predictability of the IMF corrections. Some predictability is present in our corrections – because the consolidation episodes selected are those designed to offset an expansionary increase in government spending happened in the past – but this predictability does not affect the consistency of our estimates of the output effect of fiscal adjustment plans.

Jorda and Taylor (2013), choose a different route to address the predictability of the $\epsilon^\text{IMF}_{i,t}$ corrections, by taking the following three steps:

- redefine $\epsilon^\text{IMF}_{i,t}$ innovations as a 0/1 dummy variable;
- estimate a propensity score deriving the probability with which a correction is expected by regressing it on its own past and predictors;
- use the propensity score to derive an Average Treatment Effect based on Inverse Probability Weighting.

This method has the advantage of taking the simulation of the output effect of fiscal adjustments closer to a quasi-natural experiment. This result, however, comes at some cost. First, replacing $\epsilon^\text{IMF}_{i,t}$ innovations with a 0/1 dummy disregards relevant information on the intensity of the adjustment. Second, the links between the announced and anticipated part of a stabilization plan are lost. Third, the presence of the forward looking component – which is omitted from the specification – might introduce a bias in the local-projections-computed impulse responses whenever there is a systematic relation between the forward looking component and the unexpected component of the adjustment. Fourth, the heterogeneity of fiscal plans across countries is lost when they are assimilated to the same common treatment administered to many “patients”.
